(Dated: December 3, 2012)

We introduce a circuit quantum electrodynamical setup for a quantum single photon transistor. In our approach single photons propagate in two open transmission lines that are coupled via two interacting transmon qubits. The interaction is such that photons are not exchanged between the two transmission lines but a photon in one line can completely block respectively enable the propagation of photons in the other line. High on-off ratios can be achieved for feasible experimental parameters. Our approach is inherently scalable as all photon pulses can have the same pulse shape and carrier frequency such that output signals of one transistor can be input signals for a consecutive transistor.

PACS numbers: 42.50.Ex,85.25.Cp,42.25.Fx,42.50.Nn

Photons are the most suitable carrier for transmitting information over long distances as they are largely immune to environmental perturbations, and can propagate with very low loss and long-lived coherence in a wide range of media [1]. The use of photons in information processing however still suffers from the inability to realize controlled, strong interactions between individual photons. To make photons a more versatile information carrier, it is therefore of great importance to conceive means of making photonic signals interact with each other [2]. In vacuum, direct photon-photon interactions are absent. Nonetheless, optical signals can influence each other in nonlinear media. Yet, the quantum regime with interactions between individual photons only becomes accessible for devices where optical nonlinearities exceed incoherent and dissipative processes. Such devices therefore require a strong coupling of the photons to the material that mediates the effective photon-photon interactions. Since the coupling of light to matter can be enhanced if light fields are confined to small volumes in space, cavities and one-dimensional waveguides are prime candidates for such devices.

Here we introduce a scheme for a quantum single photon transistor, a device that can be considered to form a cornerstone of quantum optical information processing. In our approach individual photons propagate in two one-dimensional waveguides of low transverse dimension and scatter off each other at a localized scattering center formed by two two-level systems (qubits) that each couple to one of the waveguides, see figure 1a. The qubits interact in such a way that no excitations can be exchanged between them and thus ensure that each photon remains in its initial waveguide after the scattering event. Nonetheless, as we show below, the presence of a single photon in one waveguide can completely block or enable the propagation of a photon in the other waveguide. Importantly, our approach considers propagating light signals that all have the same carrier frequency and is thus inherently scalable as the output signals of one transistor can enter as input signals into a consecutive transistor, c.f. figure 1c for an illustration. Such scalability is questionable in previous proposals which are based on different technological platforms [3, 4]. Moreover the device we propose is a passive element that does not require any temporal tuning. This implies that the arrival time of the photons at the scattering center can be completely unknown.

A technology that is ideally suited for realizing the device we envision is provided by itinerant microwave photons in superconducting circuits [5, 6]. Here, coherent scattering at a superconducting qubit [7–9] and entanglement with a qubit [10] have been demonstrated for individual photons that propagate in open transmission lines. Moreover precise shaping of single photons pulses has been shown [11] very recently. An implementation of our approach in circuit quantum electrodynamics thus requires two superconducting qubits that are coupled to open transmission lines. We show that the desired qubit-qubit interaction can be realized with two transmon qubits [12] that are coupled via a SQUID which can be tuned to ensure that no excitations are exchanged between both transmons. Importantly, this coupling is not dispersive [13] and thus strong as both transmons have the same transition frequency. These rather unique possibilities for qubit-qubit interactions offered by superconducting circuits are very suitable for our aims. Moreover, their robustness with respect to dephasing noise make transmons ideal qubits for our device. Yet, alternatively one could also use two flux qubits that are coupled via an induction loop [14, 15].

To demonstrate the capabilities of the single photon transistor we propose, we provide results for the photon reflection and transmission spectra and probabilities for both transmission lines, which depend on the incoming single or two-photon pulses. Furthermore, we determine the achievable strength of photon-photon interactions under realistic experimental conditions, i.e. taking into account all dissipative processes in our setup.

Setup We consider two interacting qubits that each couple to a one-dimensional waveguide in which the photons propagate. Here we focus on a setup for which we can refer to a control and a target photon, where the

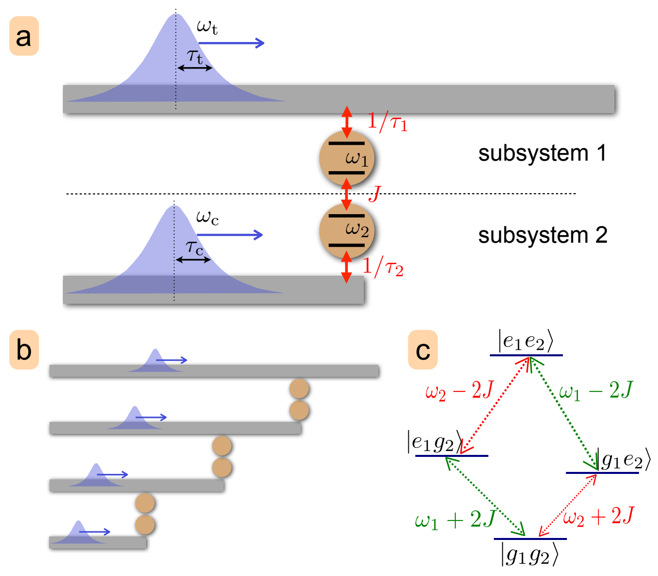

FIG. 1: Sketch of the considered setup. **a**) Two photons traveling in separate waveguides scatter off each other at a scattering center formed by two interacting qubits. **b**) Since all photons have the same frequency, multiple devices can be concatenated to form a network. **c**) Level scheme of the scattering center Hamiltonian H_{sys}, c.f. equation (1).

presence of the control photon influences the target photon's direction of propagation, while the control photon's direction of propagation always changes. A sketch of this setup is shown in figure 1. The control photon propagates in the waveguide of subsystem 2, c.f. figure 1, which has a closed end right where it couples to qubit 2. This arrangement enhances the absorption of photons by qubit 2 and hence its inversion as compared to an open waveguide end, a property that is not necessary but beneficial for our aims. The control photon is thus always reflected. The target photon in turn propagates in the waveguide of subsystem 1. The qubit-qubit interaction is such that no excitations are exchanged between the two qubits. This implies that a photon in one waveguide can not tunnel to the other waveguide and vice versa. Nonetheless one control photon in waveguide 2 can completely block respectively enable the propagation of a target photon in waveguide 1 as we show below. The Hamiltonian of the two coupled qubits reads,

$$H_{sys} = \frac{\omega_1}{2}\sigma_1^z + \frac{\omega_2}{2}\sigma_2^z - J\sigma_1^z\sigma_2^z\,, \tag{1}$$

where the σ_i^z are Pauli-operators, ω_1 and ω_2 the transition frequencies of the two qubits and J the strength of their mutual interaction. This Hamiltonian can be implemented with two transmon qubits that are coupled via a SQUID, see figure 3 and supplementary material [16], or with two inductively coupled flux qubits [14, 15].

Both waveguides respectively transmission lines have a continuous spectrum of photonic modes and can be described by the Hamiltonian [20], $H_T = \int_{-\infty}^{\infty} dp\, p\, (r_p^\dagger r_p - l_p^\dagger l_p) + \int_{-\infty}^{\infty} dp\, p\, b_p^\dagger b_p$, where $r_p^\dagger$ ($l_p^\dagger$) creates a photon in subsystem 1 which travels to the right (left) and $b_p^\dagger$ creates a photon in subsystem 2. $p = v_g\eta$ where v_g is the group velocity and the wave vector η is negative (positive) for left (right) going modes. The transmission line of subsystem 2 is cut and can be described by only one continuum of modes since the incoming and outgoing modes of a semi-infinite transmission line can be mapped to an infinite waveguide where photons only propagate in one direction [17].

The dispersion relation of a transmission line is linear and the frequency integration can be extended to ±∞ since we only consider single photon pulses with a frequency width that is much smaller than their carrier frequency. For these narrow linewidth pulses we thus take the photon-qubit coupling to be independent of the photon frequency,

$$\begin{aligned} H_I =& \frac{1}{\sqrt{2\pi\tau_1}}\int_{-\infty}^{\infty} dp[\sigma_1^+(r_p + l_p) + \sigma_1^-(r_p^\dagger + l_p^\dagger)] \\ &+ \frac{1}{\sqrt{\pi\tau_2}}\int_{-\infty}^{\infty} dp[\sigma_2^+ b_p + \sigma_2^- b_p^\dagger]. \end{aligned} \tag{2}$$

Here τ_1 and τ_2 are the lifetimes of the two level systems associated to their coupling to the transmission lines. A further benefit of the semi-infinite waveguide in subsystem 2 is the $\sqrt{2}$ enhancement of the coupling in H_I. Figure 1b shows the level scheme of the two qubits described by H_{sys} and the transitions induced by the photons.

In a realistic system, the qubits will be subject to dissipation. We thus consider for each qubit a coupling to an environment which we model as a continuum of bosonic modes with creation operators $c_p^\dagger$ respectively $d_p^\dagger$ and the Hamiltonian $H_B = \int_{-\infty}^{\infty} dp\, p\, c_p^\dagger c_p + \int_{-\infty}^{\infty} dp\, p\, d_p^\dagger d_p$. The coupling of the qubits to their environments reads $H_{BI} = \sqrt{\gamma/\pi}\int_{-\infty}^{\infty} dp\, \left[(\sigma_1^+ c_p + \sigma_1^- c_p^\dagger) + (\sigma_2^+ d_p + \sigma_2^- d_p^\dagger)\right]$, where γ is the relaxation rate of the qubits. The total Hamiltonian that includes the environment, the transmission lines, the qubits and all couplings between these constituents thus reads,

$$H = H_T + H_{sys} + H_I + H_B + H_{BI}. \tag{3}$$

To investigate the dynamics of single photon pulses in this setup, we combine quantum scattering theory [18] with the input-output formalism [19] of quantum optics as in [20], see supplementary material [16] for details. For the dynamics of the qubit operators, including dissipative processes, we derive quantum Langevin equations [21] starting from the Hamiltonian (3). The solutions of these yield the source terms for the input-output relations which we then relate to the scattering matrix [16].

Photon-Photon Interaction To see the effect of the photon-photon interaction most clearly, we first consider the situation in which only one target photon but no control photon is present. An incoming target photon that travels to the right is described by $|\Psi_{\mathrm{t}}\rangle = \int dk\, \alpha_{\mathrm{t}}(k)\, r^{\dagger}(k)|0\rangle$, where k labels the frequency components. We assume for the target photon a pulse with a Lorentzian frequency distribution, $\alpha_{\mathrm{t}}(k) = \{\sqrt{\pi\tau_{\mathrm{t}}}\,[\mathrm{i}(\omega_{\mathrm{t}} - k) + \tau_{\mathrm{t}}^{-1}]\}^{-1}$. Here τ_{t} is the temporal width of the pulse and ω_{t} its carrier frequency. A pulse of this form would for example describe a photon that was spontaneously emitted into the transmission line from an excited qubit as experimentally realized in [22]. We here chose to operate the transistor such that the target photon is reflected in the absence but unaffected in the presence of the control photon and choose ω_{t} to be equal to the frequency of the transition $|g_1 g_2\rangle \to |e_1 g_2\rangle$ ($|g_j\rangle/|e\rangle_j$ denotes qubit j in the ground/excited state), i.e. $\omega_{\mathrm{t}} = \omega_1 + 2J$. The reverse mode of operation where the target photon is unaffected in the absence and reflected in the presence of the control photon can be selected by choosing $\omega_{\mathrm{t}} = \omega_1 - 2J$ and works equally well. Without control photon evidently no photon-photon interaction can take place and the output state reads, $|\Psi_{\mathrm{out}}\rangle = \int dp \sum_{i=r,l,c} \beta_i(p) i_p^{\dagger}|0\rangle$, where the transmission amplitude is denoted $\beta_r(p)$, the reflection amplitude $\beta_l(p)$ and the amplitude for the target photon being lost $\beta_c(p)$. These amplitudes relate to the initial state via $\beta_i(p) = \int dk\, \alpha_{\mathrm{t}}(k)\, S_i(k,p)$, where the $S_i(k,p)$ are the S-matrix elements for the different processes, see supplementary material [16]. The resulting transmission probability for the target photon reads,

$$p_T = \frac{\tau_1 + \tau_1^2\gamma + (\tau_1\gamma)^2\tau_{\mathrm{t}}}{(1+\tau_1\gamma)(\tau_1 + \tau_{\mathrm{t}} + \tau_{\mathrm{t}}\tau_1\gamma)} \tag{4}$$

and the reflection probability $p_R = \tau_{\mathrm{t}}/(1+\tau_1\gamma)(\tau_1 + \tau_{\mathrm{t}} + \tau_{\mathrm{t}}\tau_1\gamma)$. We note that $p_T + p_R < 1$ because the photon can also be lost due to qubit relaxation. Importantly, in the regime of $\gamma^{-1} \gg \tau_{\mathrm{t}} \gg \tau_1$, the reflection probability for the target photon approaches unity [3].

Next we consider the case of the same incident target photon but now in the presence of an incoming control photon. As the control photon inverts qubit 2, the scattering center is in the state $|g_1 e_2\rangle$ and the target photon can only couple to the transition $|g_1 e_2\rangle \to |e_1 e_2\rangle$, see figure 1b. This transition is detuned by $4J$ from the target photon frequency, and thus the transmission probability for the target photon approaches unity if J is large compared to the linewidths of target pulse and qubit 1, $J \gg \tau_1^{-1} + \tau_{\mathrm{t}}^{-1}$. Our scheme works best if the control photon pulse is chosen such that it maximally inverts qubit 2. A suitable pulse is thus the time reversed version of a pulse resulting from spontaneous emission of qubit 2 into the transmission line [23] which is often called an inverting pulse [24]. The generation of inverting pulses and their release into a transmission line was demonstrated recently [11]. For the cut transmission line in subsystem 2 an inverting pulse of carrier frequency ω_{c} and temporal width τ_{c} thus reads $|\Psi_{\mathrm{c}}\rangle = \int dk\, \alpha_{\mathrm{c}}(k)\, b_k^{\dagger}|0\rangle$ with $\alpha_{\mathrm{c}}(k) = \{\sqrt{\pi\tau_{\mathrm{c}}}\,[-\mathrm{i}(\omega_{\mathrm{c}} - k) + \tau_{\mathrm{c}}^{-1}]\}^{-1}$. We note that our results do not change if the target photon pulse also has the shape of an inverting pulse so that our scheme is indeed scalable. Due to the coupling to vacuum, the qubit 2 is of course never completely inverted. The output state reads, $|\Psi_{\mathrm{out}}\rangle = \int dp_1 dp_2 \sum_{i=r,l,c} \sum_{j=b,d} \beta_{i,j}(p_1,p_2) i^{\dagger}(p_1) j^{\dagger}(p_2)|0\rangle$. The first index in the amplitudes $\beta_{i,j}(p_1,p_2)$ refers to the target photon, which can be reflected, l, transmitted, r, or lost, c, and the second index refers to the control photon which can be reflected, b, or lost, d. For the probability of the target photon being transmitted in the presence of a control photon we thus get,

$$p_{TC} = \int dp_1 dp_2 \left[|\beta_{r,b}(p_1,p_2)|^2 + |\beta_{r,d}(p_1,p_2)|^2 \right]. \tag{5}$$

We now quantify the performance of the single photon transistor we propose via the difference C_s and ratio R_s between the transmission probabilities for the target photon in the presence and absence of a control photon,

$$C_s = p_{TC} - p_T \quad \text{and} \quad R_s = p_{TC}/p_T, \tag{6}$$

where p_{TC} and p_T are given in equations (4) and (5) respectively. For $C_s = 1$ the setup would describe an ideal quantum transistor for single photons. Figure 2 shows the achievable transmission contrast, C_s, and on-off ratio, R_s, for a realistic device with given qubit-qubit coupling of $J = 0.01\,\omega_1$ as a function of the qubit decay rate γ. As the plot shows, an ideal single photon transistor can be realized in the limit of vanishing γ/ω_1 whereas very good performance can already be expected for currently realized values of $J \sim 50\,\mathrm{MHz}$ and $\gamma/\omega_1 \sim 10^{-6}$ [25–27], where a single control photon changes the transmission probability of the target photon by a factor 20.

The performance of the single photon transistor we propose depends on the shapes of the target and control photon pulses and the parameters of the Hamiltonian (3). As expected the best choices for the carrier frequencies of the control and target pulses are equal to the transition frequencies of $|g_1 g_2\rangle \to |g_1 e_2\rangle$ respectively $|g_1 g_2\rangle \to |e_1 g_2\rangle$, i.e. $\omega_{\mathrm{c}} = \omega_2 + 2J$ and $\omega_{\mathrm{t}} = \omega_1 + 2J$. For a single transistor ω_1 and ω_2 may be chosen arbitrarily. Yet to enable concatenation of multiple transistors, we choose $\omega_1 = \omega_2$. Moreover the interaction of the target photon with qubit 1 should be as high as possible. We choose $\tau_1 = 20/\omega_1$ which is compatible with experiments. For a control photon which is an inverting pulse, i.e. the time reversed version of a photon that would result from a spontaneous emission process, the optimal choice for its temporal width is obviously $\tau_{\mathrm{c}} = \tau_2$. There are thus two remaining parameters, τ_{t} and τ_{c}, which we have optimized numerically. The results are shown in figures 2b and 2c, where we show the optimal choices of τ_{t} and τ_{c} as a function of γ/ω_1.

Coupled transmons As stated above, the qubit-qubit interaction in equation (1) can be realized with two

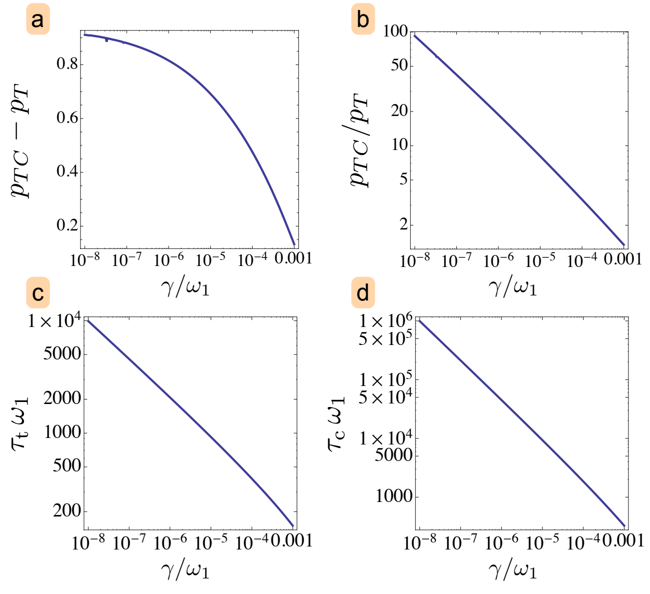

FIG. 2: Performance of the quantum single photon transistor. **a:** Maximized contrast $C_s = p_{TC} - p_T$ as a function of the inverse Q-factor of the qubits γ/ω_1 for $\omega_c = \omega_2 + 2J$, $\omega_t = \omega_1 + 2J$, $\omega_2 = \omega_1$, $\tau_1 = 20/\omega_1$, $J = 0.01\,\omega_1$ and $\tau_c = \tau_2$. **b:** On-off ratio $R_s = p_{TC}/p_T$ for the same parameters. **c:** Optimal choice of τ_t for a given γ/ω_1. **d:** Optimal choice of τ_c for a given γ/ω_1.

transmon qubits that are coupled via a SQUID. The circuit we consider is sketched in figure 3. and described by the Lagrangian [28], $\mathcal{L} = \mathcal{L}_1 + \mathcal{L}_2 + \mathcal{L}_{12}$, where the Lagrangians of the individual qubits read, $\mathcal{L}_j = \frac{C}{2}\dot{\varphi}_j^2 + \frac{C_g}{2}(\dot{\varphi}_j - V_j)^2 + E_J \cos(\varphi_j/\varphi_0)$ and $\mathcal{L}_{12} = \frac{C_m}{2}(\dot{\varphi}_1 - \dot{\varphi}_2)^2 + E_{Jm}\cos\left(\frac{\varphi_1 - \varphi_2}{\varphi_0}\right)$. Here $\varphi_0 = \hbar/(2e)$ is the flux quantum divided by 2π, C and E_J are the capacitance and Josephson energy of the individual transmons which are assumed to be identical. C_m and E_{Jm} are the capacitance and Josephson energy of the capacitively shunted coupling SQUID. The C_g are the coupling capacitances between the transmission lines and the individual transmons (also assumed to be identical) and the V_i are the fully quantum mechanical quadratures of the electric potential of the transmission line fields. All Josephson energies of the setup are tunable by threading external fluxes Φ_J and Φ_{Jm} through respective SQUID loops, c.f. figure 3. We write the corresponding Hamiltonian of the transmons in terms of creation and annihilation operators $a_j^\dagger$ and a_j [16]. By tuning E_J and E_{Jm} such that $\frac{E_{Jm}}{E_J + E_{Jm}} = \frac{C_m}{C + C_m + C_g}$, all interactions of the form $a_1 a_2^\dagger + a_1^\dagger a_2$ cancel and the leading term of the remaining interactions reads $-\frac{2E_C C_m}{(C + C_m + C_g)} a_1^\dagger a_1 a_2^\dagger a_2$ which is equivalent to the interaction in equation (1) with $J = \frac{C_m}{2(C + C_m + C_g)} E_C$. Within the approximations we use [16] the achievable qubit-qubit coupling is $J < E_C/10$.

In conclusion, we have introduced a scheme for a quantum single photon transistor in circuit quantum electrodynamics that is inherently scalable as both photons can have the same carrier frequency and pulse shape. The performance of the device might be further improved by suppressing losses with multiple, regularly spaced qubit pairs [29]. Moreover, the complexity of a network built with such transistors could be increased further by integrating directional couplers between them [30].

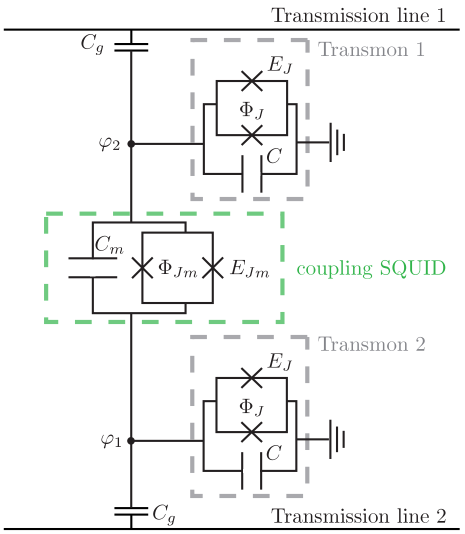

FIG. 3: Circuit model of the two coupled transmon qubits with Josephson energy E_J and shunting capacitance C. Both transmons are coupled via a combination of capacitive and inductive coupling realized with a SQUID arrangement with Josephson energy E_{Jm} and shunting capacitance C_m. The transmons are capacitively coupled to transmission lines.

SUPPLEMENTARY MATERIAL

Scattering theory and input-output relations

In this work we calculate the output states of our device for given input states by making use of a combination of scattering theory and the input-output formalism. In this approach, output and input states are connected via the scattering matrix (S-matrix),

$$|\Psi_{\mathrm{out}}\rangle = S|\Psi_{\mathrm{in}}\rangle \tag{7}$$

The S-matrix elements in turn can be written in terms of scattering operators [18]. For example for the process of transmission of a single photon, the S-matrix element reads,

$$S_r(k,p) = \langle 0|r_{\mathrm{out}}(p) r^\dagger_{\mathrm{in}}(k)|0\rangle, \tag{8}$$

where

$$r^\dagger_{\mathrm{in/out}}(\omega) = \lim_{t_0\to\mp\infty} e^{\mathrm{i}Ht_0} e^{-\mathrm{i}H_T t_0} r^\dagger(\omega) e^{\mathrm{i}H_T t_0} e^{-\mathrm{i}Ht_0}, \tag{9}$$

and $H_T = \int_{-\infty}^{\infty} dp\, p\, (r_p^\dagger r_p - l_p^\dagger l_p) + \int_{-\infty}^{\infty} dp\, p\, b_p^\dagger b_p$ is as in the main text. In turn, for a two photon process, where the target photon is transmitted and the control photon is lost in the vacuum, the S-matrix element reads,

$$S_{r,d}(k,k',p,p') = \langle 0|r_{\mathrm{out},p} d_{\mathrm{out},p'} r^\dagger_{\mathrm{in},k} b^\dagger_{\mathrm{in},k'}|0\rangle \tag{10}$$

For our system it is convenient to introduce even and odd modes for transmission line 1,

$$a_1(p) = \frac{1}{\sqrt{2}}\left(r_p + l_{-p}\right) \tag{11}$$

$$\mathring{a}_1(p) = \frac{1}{\sqrt{2}}\left(r_p - l_{-p}\right) \tag{12}$$

Due to the form of the photon-qubit coupling in equation (2) of the main text, only even modes couple to the qubit whereas odd modes completely decouple from the rest of the system and describe freely propagating photons. The coupling strength to the even modes is enhanced by a factor of $\sqrt{2}$.

To calculate the desired scattering matrix elements a link to equations of motion, i.e. the Langevin equations [19] that describe the dynamics of the scattering center is exploited. To make use of the Langevin equations, it is necessary to connect the scattering operators to standard input-output operators that fulfill the input-output relations,

$$a_{\mathrm{out}}(t) = a_{\mathrm{in}}(t) - \mathrm{i}\sqrt{\frac{2}{\tau}}\sigma_-(t), \tag{13}$$

where $a_{\mathrm{in}}(t)$ and $a_{\mathrm{out}}(t)$ are any even mode input/output operators, defined by

$$a_{\mathrm{in/out}}(t) \equiv \frac{1}{\sqrt{2\pi}} \int d\omega e^{-\mathrm{i}\omega(t-t_{0/1})} a_{0/1}(\omega). \tag{14}$$

Here, the operator $a_{0/1}(\omega)$ plays the role of an initial value in the Heisenberg picture,

$$a_{0/1}(\omega) = e^{\mathrm{i}Ht_{0/1}} a(\omega) e^{-\mathrm{i}Ht_{0/1}} \tag{15}$$

The corresponding input and output scattering operators for even modes are defined as in equation (9),

$$\begin{aligned} a_{\mathrm{in/out}}(\omega) &= \lim_{t_0\to\mp\infty} e^{\mathrm{i}Ht_0} e^{-\mathrm{i}H_T t_0} a(\omega) e^{\mathrm{i}H_T t_0} e^{-\mathrm{i}Ht_0} \\ &= \lim_{t_0\to\mp\infty} e^{\mathrm{i}\omega t_0} e^{\mathrm{i}Ht_0} a(\omega) e^{-\mathrm{i}Ht_0}, \end{aligned} \tag{16}$$

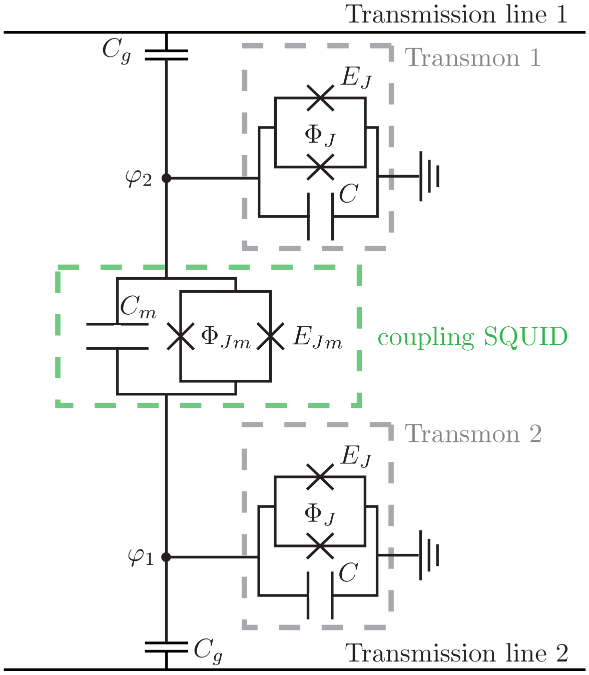

FIG. 4: Circuit model of the pair of transmons with Josephson energy E_J and shunting capacitance C. Both transmons are coupled via a combination of capacitive and inductive coupling realized with a SQUID arrangement with Josephson energy E_{Jm} and shunting capacitance C_m. The transmons are capacitively coupled to transmission lines and all Josephson energies of the setup are tunable by threading external fluxes Φ_J and Φ_{Jm} through respective SQUID loops.

where we have made use of the Baker-Campbell-Hausdorff formula. We now solve equation (16) for $a(\omega)$ and plug the result into equation (14) by making use of equation (15). Taking the limits $t_0 \to -\infty$ respectively $t_1 \to +\infty$ in equation (14) we find that the scattering operator $a_{\rm in}(\omega)$ is the Fourier transform of the Heisenberg operator $a_{\rm in}(t)$ in the limit $t_0 \to -\infty$ and that the the scattering operator $a_{\rm out}(\omega)$ is the Fourier transform of the Heisenberg operator $a_{\rm out}(t)$ in the limit $t_1 \to +\infty$ [20],

$$a_{\rm in/out}(t) = \frac{1}{\sqrt{2\pi}} \int d\omega a_{\rm in/out}(\omega) e^{-{\rm i}\omega t} \tag{17}$$

Using equation (17) we express the scattering matrix S in terms of input and output operators which are found from solutions of the Langevin equations that describe the dynamics of the scattering center.

Coupled Transmons

The Lagrangian describing the two transmons that are mutually coupled via a SQUID and each couple to a transmission line reads,

$$\begin{aligned}\mathcal{L} &= \frac{C}{2}\left(\dot\varphi_1^2 + \dot\varphi_2^2\right) + \frac{C_m}{2}\left(\dot\varphi_1 - \dot\varphi_2\right)^2 \\ &+ \frac{C_g}{2}(\dot\varphi_1 - V_1)^2 + \frac{C_g}{2}(\dot\varphi_2 - V_2)^2 \\ &+ E_J\left[\cos\left(\frac{\varphi_1}{\varphi_0}\right) + \cos\left(\frac{\varphi_2}{\varphi_0}\right)\right] \\ &+ E_{Jm}\cos\left(\frac{\varphi_1 - \varphi_2}{\varphi_0}\right)\end{aligned} \tag{18}$$

where $\varphi_0 = \hbar/(2e)$ is the flux quantum divided by 2π, C and E_J are the capacitance and Josephson energy of the individual transmons which are assumed to be identical. C_m and E_{Jm} are the capacitance and Josephson energy of the capacitively shunted coupling SQUID. The C_g are the coupling capacitances between the transmission lines and the individual transmons (also assumed to be identical) and the V_i are the fully quantum mechanical electric potential quadratures of the transmission line fields. Hence, the corresponding Hamiltonian reads,

$$\begin{aligned}H &= 4E_C\left(n_1^2 + n_2^2 + 2\frac{C_m}{C + C_g + C_m}n_1 n_2\right) \\ &+ 8E_C n_{g,1}\left(n_1 + \frac{C_m}{C + C_g + C_m}n_2\right) \\ &+ 8E_C n_{g,2}\left(\frac{C_m}{C + C_g + C_m}n_1 + n_2\right) \\ &- E_J\left(\cos\phi_1 + \cos\phi_2\right) - E_{Jm}\cos(\phi_1 - \phi_2),\end{aligned} \tag{19}$$

where $\phi_i = \varphi_i/\varphi_0$, $n_{g,i} = \varphi_0 C_g V_i$ for $i = 1, 2$ and $E_C = \frac{\hbar^2}{8\varphi_0^2}\frac{C+C_g+C_m}{(C+C_g)(C+C_g+2C_m)}$. The secondary capacitive coupling between transmission line 1 and transmon 2 and vice versa is small compared to the other couplings since $C_m/(C + C_g + C_m) \ll 1$. We thus neglect such couplings and obtain for the coupling between the transmission lines and the transmons,

$$H_g = 8E_C(n_{g,1}n_1 + n_{g,2}n_2) \tag{20}$$

We furthermore separate the Josephson terms into local and nonlocal terms,

$$\begin{aligned}E_{Jm}\cos(\phi_1 - \phi_2) &= E_{Jm}\underbrace{(\cos\phi_1 + \cos\phi_2)}_{\text{local}} \\ +E_{Jm}&\underbrace{[(\cos\phi_1 - 1)(\cos\phi_2 - 1) + \sin\phi_1\sin\phi_2]}_{\text{nonlocal}},\end{aligned} \tag{21}$$

where we have added an irrelevant constant. This leaves us with the local Hamiltonians for each transmon ($i = 1, 2$),

$$H_i = 4E_C n_i^2 - \overline{E}_J\cos\phi_i, \tag{22}$$

where $\overline{E}_J = E_J + E_{Jm}$ and the coupling Hamiltonian,

$$\begin{aligned}H_{12} &= 8E_C\frac{C_m}{C + C_g + C_m}n_1 n_2 \\ &- E_{Jm}\left[(\cos\phi_1 - 1)(\cos\phi_2 - 1) + \sin\phi_1\sin\phi_2\right]\end{aligned} \tag{23}$$

We describe the transmons in the approved approximation with anharmonic oscillators [12] and introduce raising and lowering operators $a_i^\dagger$ and a_i via

$$n_i = \frac{i}{2}\left(\frac{\overline{E}_J}{2E_C}\right)^{\frac{1}{4}}(a_i - a_i^\dagger) \tag{24}$$

$$\phi_i = \left(\frac{2E_C}{\overline{E}_J}\right)^{\frac{1}{4}}(a_i + a_i^\dagger) \tag{25}$$

Keeping only the leading nonlinear terms we thus find,

$$H_i \approx \sqrt{8E_C\overline{E}_J}\, a_i^\dagger a_i - \frac{E_C}{2}\, a_i^\dagger a_i^\dagger a_i a_i \tag{26}$$

We are interested in a scenario where tunneling of excitations from one transmon to the other is strongly suppressed. The leading tunneling terms are found by expanding the coupling Hamiltonian H_{12} to linear order in a_1 and a_2. With a rotating wave approximation we find,

$$\begin{aligned} &8E_C\frac{C_m}{C+C_g+C_m}n_1n_2 - E_{Jm}\phi_1\phi_2 \approx \qquad (27)\\ &\approx \sqrt{\frac{2E_C}{\overline{E}_J}}\left(\overline{E}_J\frac{C_m}{C+C_g+C_m} - E_{Jm}\right)(a_1a_2^\dagger + a_1^\dagger a_2) \end{aligned}$$

These terms vanish if one chooses the external fluxes that control the values of E_J and E_{Jm} such that,

$$\frac{E_{Jm}}{E_J + E_{Jm}} = \frac{C_m}{C + C_m + C_g} \tag{28}$$

The rotating wave approximation applied for deriving equation (27) furthermore requires that $E_{Jm} < 2E_J/3$.

The desired density-density interaction is contained in the nonlocal cosine interaction terms,

$$H_J = -\frac{E_{Jm}}{4}\phi_1^2\phi_2^2 \approx -2E_C\frac{E_{Jm}}{E_J + E_{Jm}}a_1^\dagger a_1 a_2^\dagger a_2 \tag{29}$$

Here we have applied a rotating wave approximation and made use of the fact that our initial states only contain one photon per transmission line which allows us to neglect terms of the form $a_1a_1a_2^\dagger a_2^\dagger$ + H.c.. Since the dynamics of our system is, for the initial state we consider, restricted to the subspace of at most one excitation per transmon respectively transmission line we can write our Hamiltonian in terms of Pauli matrices,

$$H^{2\times 2} = H_{sys} + H_g^{2\times 2} \tag{30}$$

where H_{sys} is as in equation (1) of the main text with $\omega = \sqrt{8E_C\overline{E}_J} + \delta\omega$, where $\delta\omega$ accumulates all minor renormalizations of the transmon frequencies due to the nonlinear terms of the cosine potentials and

$$J = \frac{C_m}{2(C + C_m + C_g)}E_C. \tag{31}$$

Since $C_m/(C + C_g + C_m) \ll 1$ we find the upper limit,

$$J < \frac{1}{10}E_C, \tag{32}$$

for the strength of the qubit-qubit interaction. In turn the couplings to the transmission lines read,

$$H_g^{2\times 2} = 4iE_C\left(\frac{\overline{E}_J}{2E_C}\right)^{\frac{1}{4}}\sum_{j=1,2} n_{g,j}(\sigma_j^+ - \sigma_j^-),$$

which become identical to equation (2) after applying a rotating wave approximation.
